Data-Parallel Thinking
Today’s theme

- Many of you are likely accustomed to thinking about parallel programming in terms of “what workers do”

- Today I would like you to think about describing algorithms in terms of operations on sequences of data:
  - map
  - filter
  - fold / reduce
  - scan / segmented scan
  - sort
  - groupBy
  - join
  - partition / flatten

- Main idea: high-performance implementations of these operations exist. So programs written in terms of these primitives can often run efficiently on a parallel machine
Motivation

▪ Why must an application expose large amounts of parallelism?

▪ Utilize large numbers of cores
  - High core count machines
  - Many machines (e.g., cluster of machines in the cloud)
  - SIMD processing + multi-threaded cores require even more parallelism
  - GPU architectures require very large amounts of parallelism
Recall: geometry of the GTX1080 GPU

- **L2 Cache (2 MB)**
- **320 GB/sec**
- **GPU memory (DDR5 DRAM)**
- **1.6 GHz clock**
- **20 SM/cores per chip**
- **20 \times 128 = 2,560 SIMD mul-add ALUs = 8.1 TFLOPs**
- **Upto 20 \times 64 = 1280 interleaved warps per chip (40,960 CUDA threads/chip)**
- **TDP: 180 watts**

This chip can concurrently execute up to 40,960 CUDA threads! (programs that do not expose significant amounts of parallelism will not run efficiently on GPUs!)

*They need high arithmetic intensity as well.*
Key part of parallel programming is understanding when dependencies exist between operation

Lack of dependencies implies potential for parallel execution

\[
x = a + b; \\
y = b \times 7; \\
z = (x-y) \times (x+y);
\]
Data-parallel model

- Organize computation as operations on sequences of elements
  - e.g., perform same function on all elements of a sequence

- Historically: same operation on each element of an array
  - Matched capabilities SIMD supercomputers of 80’s
  - Connection Machine (CM-1, CM-2): thousands of processors, one instruction decode unit
  - Early Cray supercomputers were vector processors
    - add(A, B, n) ← this was one instruction on vectors A, B of length n

- A well-known modern example: NumPy: C = A + B
  (A, B, and C are vectors of same length)
**Key data type: sequences**

- Ordered collection of elements
- For example, in a C++ like language: `Sequence<T>`
- e.g., Scala lists: `List[T]`
- In a functional language (like Haskell): `seq T`

- Important: programs can only access elements of a sequence through specific operations
Map

- Higher order function (function that takes a function as an argument)
- Applies side-effect free unary function \( f :: a \rightarrow b \) to all elements of input sequence, to produce output sequence of the same length

In a functional language (e.g., Haskell)
- \( \text{map} :: (a \rightarrow b) \rightarrow \text{seq } a \rightarrow \text{seq } b \)

In C++:
\[
\text{template}<\text{class } \text{InputIt}, \text{class } \text{OutputIt}, \text{class } \text{UnaryOperation}>
\text{OutputIt } \text{transform}(\text{InputIt } \text{first1}, \text{InputIt } \text{last1},
    \text{OutputIt } \text{d_first},
    \text{UnaryOperation } \text{unary_op});
\]
Parallelizing map

- Since \( f : : a \to b \) is a function (side-effect free), then applying \( f \) to all elements of the sequence can be done in any order without changing the output of the program.

- The implementation of map has flexibility to reorder/parallelize processing of elements of sequence however it sees fit.

\[
\begin{align*}
\text{map } f \ s &= \\
\text{partition sequence } s \text{ into } P \text{ smaller sequences for each subsequence } s_i \text{ (in parallel)} \\
\text{out}_i &= \text{map } f \ s_i \\
\text{out} &= \text{concatenate out}_i's
\end{align*}
\]
Fold (fold left)

- Apply f to each element and an accumulated value
  - Seeded by initial value of type b

- \( f :: (b, a) \rightarrow b \)
- \( \text{fold} :: b \rightarrow ((b, a) \rightarrow b) \rightarrow \text{seq} \ a \rightarrow b \)

E.g., in Scala:
```scala
def foldLeft[A, B](init: B, f: (B, A) => B, l: List[A]): B
```

![Diagram of fold left operation](image)
Parallel fold

- Apply \( f \) to each element and an accumulated value
  - Seeded by initial value of type \( b \) (identity for \( f \) and \( \text{comb} \))
  - \( f ::= (b,a) \to b \)
  - \( \text{comb} ::= (b,b) \to b \)
  - \( \text{fold} \_\text{par} ::= b \to ((b,a) \to b) \to ((b,b) \to b) \to \text{seq} \ a \to b \)
Scan

- \( f :: (a, a) \rightarrow a \) (associative binary op)
- \( \text{scan} :: a \rightarrow ((a, a) \rightarrow a) \rightarrow \text{seq} \ a \rightarrow \text{seq} \ a \)

```c
scan_inclusive(float* in, float* out, int N) {
    out[0] = in[0];
    for (i=1; i<N; i++)
        out[i] = op(out[i-1], in[i-1]);
}
```

"Exclusive": the value of \( \text{out}[i] \) is the scan result for all elements up to, but excluding, \( \text{in}[i] \).
Parallel Scan
Data-parallel scan

let $A = [a_0, a_1, a_2, a_3, \ldots, a_{n-1}]$

let $\oplus$ be an associative binary operator with identity element $I$

$\text{scan\_inclusive}(\oplus, A) = [a_0, a_0 \oplus a_1, a_0 \oplus a_1 \oplus a_2, \ldots]$

$\text{scan\_exclusive}(\oplus, A) = [I, a_0, a_0 \oplus a_1, \ldots]$

If operator is $+$, then $\text{scan\_inclusive}(+, A)$ is called “a prefix sum”

$\text{prefix\_sum}(A) = [a_0, a_0 + a_1, a_0 + a_1 + a_2, \ldots]$
Data-parallel inclusive scan

(Subtract original vector to get exclusive scan result: not shown)

Work: O(N lg N)
Span: O(lg N)

Inefficient compared to sequential algorithm!

* not showing all dependencies in last step
Work-efficient parallel exclusive scan (O(N) work)
Workefficient exclusive scan algorithm

(with $\oplus = \text{“+”})$

Up-sweep:
for $d=0$ to $(\log_2 n - 1)$ do for all $k=0$ to $n-1$ by $2^{d+1}$ do
\[ a[k + 2^{d+1} - 1] = a[k + 2^d - 1] + a[k + 2^{d+1} - 1] \]

Down-sweep:
\[ x[n-1] = 0 \]
for $d=(\log_2 n - 1)$ down to $0$ do for all $k=0$ to $n-1$ by $2^{d+1}$ do
\[ \text{tmp} = a[k + 2^d - 1] \]
\[ a[k + 2^d - 1] = a[k + 2^{d+1} - 1] \]
\[ a[k + 2^{d+1} - 1] = \text{tmp} + a[k + 2^{d+1} - 1] \]

Work: $O(N)$ (but what is the constant?)
Span: $O(\lg N)$ (but what is the constant?)
Locality: ??
Now consider scan implementation on just two cores.
Exclusive scan: two processor implementation

Let base = a₀ - 7

P1

Sequential scan on elements [0-7]

Add base to elements a₈ thru a₈-11

P2

Sequential scan on elements [8-15]

Add base to elements a₈-12 thru a₈-15

Work: O(N)  (but constant is now only 1.5)

Data-access:
- Very high spatial locality (contiguous memory access)
- P1’s access to a₈ through a₈-11 may be more costly on large core count ‘NUMA’ system, but on small-scale multi-core system the access cost is likely the same as from P2
**Exclusive scan: CUDA implementation**

Example: perform exclusive scan on 32-element array: SPMD program, assume 32-wide SIMD execution

When `scan_warp` is run by a group of 32 CUDA threads, each thread returns the exclusive scan result for element `idx`

(also: upon completion `ptr[]` stores inclusive scan result)

```c++
device int scan_warp(volatile int *ptr, const unsigned int idx) {
    const unsigned int lane = idx & 31; // index of thread in warp (0..31)

    if (lane >= 1) ptr[idx] = ptr[idx - 1] + ptr[idx];
    if (lane >= 2) ptr[idx] = ptr[idx - 2] + ptr[idx];
    if (lane >= 4) ptr[idx] = ptr[idx - 4] + ptr[idx];
    if (lane >= 8) ptr[idx] = ptr[idx - 8] + ptr[idx];
    if (lane >= 16) ptr[idx] = ptr[idx - 16] + ptr[idx];

    return (lane > 0) ? ptr[idx-1] : 0;
}
```

**Work:**

??
Exclusive scan: CUDA implementation

CUDA thread index of caller

```c
device int scan_warp(volatile int *ptr, const unsigned int idx)
{
    const unsigned int lane = idx & 31; // index of thread in warp (0..31)

    if (lane >= 1) ptr[idx] = ptr[idx - 1] + ptr[idx];
    if (lane >= 2) ptr[idx] = ptr[idx - 2] + ptr[idx];
    if (lane >= 4) ptr[idx] = ptr[idx - 4] + ptr[idx];
    if (lane >= 8) ptr[idx] = ptr[idx - 8] + ptr[idx];
    if (lane >= 16) ptr[idx] = ptr[idx - 16] + ptr[idx];

    return (lane > 0) ? ptr[idx-1] : 0;
}
```

Work: $N \lg(N)$

Work-efficient formulation of scan is not beneficial in this context because it results in low SIMD utilization. It would require more than 2x the number of instructions as the implementation above!
Building scan on larger array

Example: 128-element scan using four-warp thread block
Multi-threaded, CUDA implementation

Example: cooperating threads in a CUDA thread block perform scan

Code assumes length of array given by ptr is same as number of threads per block.

```c
__device__ void scan_block(volatile int *ptr, const unsigned int idx)
{
    const unsigned int lane = idx & 31;  // index of thread in warp (0..31)
    const unsigned int warp_id = idx >> 5;  // warp index in block

    int val = scan_warp(ptr, idx);  // Step 1. per-warp partial scan
    // (Performed by all threads in block, with threads in same warp communicating through shared memory buffer ‘ptr’)
    if (lane == 31) ptr[warp_id] = ptr[idx];  // Step 2. thread 31 in each warp copies partial-scan bases in per-block shared mem
    __syncthreads();

    if (warp_id == 0) scan_warp(ptr, idx);  // Step 3. scan to accumulate bases
    // (only performed by warp 0)
    __syncthreads();

    if (warp_id > 0)  // Step 4. apply bases to all elements
        __syncthreads();ptr[warp_id-1];
    __syncthreads();

    ptr[idx] = val;
}
```

CUDA thread index of caller
Building a larger scan

Example: one million element scan (1024 elements per block)

Exceeding 1 million elements requires partitioning phase two into multiple blocks
Scan implementation

- **Parallelism**
  - Scan algorithm features O(N) parallel work
  - But efficient implementations only leverage as much parallelism as required to make good utilization of the machine
    - Goal is to reduce work and reduce communication/synchronization

- **Locality**
  - Multi-level implementation to match memory hierarchy
    (CUDA example: per-block implementation carried out in local memory)

- **Heterogeneity in algorithm**: different strategy for performing scan at different levels of the machine
  - CUDA example: different algorithm for intra-warp scan than inter-thread scan
  - Low-core count CPU example: based largely on sequential scan
Parallel Segmented Scan
Segmented scan

- Common problem: operating on sequence of sequences
- Examples:
  - For each vertex in a graph:
    - For each edge incoming to vertex:
  - For each particle in simulation
    - For each particle within cutoff radius
  - For each document in a collection
  - For each word in document
- There are two levels of parallelism in the problem that a programmer might want to exploit
- But its irregular: the size of edge lists, particle neighbor lists, words per document, etc, may be very different from vertex to vertex (or particle to particle)
Segmented scan

- Generalization of scan
- Simultaneously perform scans on arbitrary contiguous partitions of input collection

```
let A = [[1,2],[6],[1,2,3,4]]
let ⊕ = +

segmented_scan_exclusive(⊕,A) = [[0,1], [0], [0,1,3,6]]
```

Assume a simple “start-flag” representation of nested sequences:

A = [[1,2,3],[4,5,6,7,8]]
flag: 1 0 0 1 0 0 0 0
data: 1 2 3 4 5 6 7 8
Work-efficient segmented scan

(with $\oplus = "+"")

**Up-sweep:**
for d=0 to $(\log_2 n - 1)$ do:
    forall k=0 to n-1 by $2^{d+1}$ do:
        if flag[k + $2^{d+1} - 1$] == 0:
            data[k + $2^{d+1} - 1$] = data[k + $2^d - 1$] + data[k + $2^{d+1} - 1$]
            flag[k + $2^{d+1} - 1$] = flag[k + $2^d - 1$] || flag[k + $2^{d+1} - 1$]

**Down-sweep:**
data[n-1] = 0
for d=$(\log_2 n - 1)$ down to 0 do:
    forall k=0 to n-1 by $2^{d+1}$ do:
        tmp = data[k + $2^d - 1$]
        data[k + $2^d - 1$] = data[k + $2^{d+1} - 1$]
        if flag_original[k + $2^d$] == 1:  # must maintain copy of original flags
            data[k + $2^{d+1} - 1$] = 0
        else if flag[k + $2^d - 1$] == 1:  # start of segment
            data[k + $2^{d+1} - 1$] = tmp
        else:
            data[k + $2^{d+1} - 1$] = tmp + data[k + $2^{d+1} - 1$]
            flag[k + $2^d - 1$] = 0
### Segmented scan (exclusive)

---

Segmented scan (exclusive)
Sparse matrix multiplication example

\[
\begin{bmatrix}
  y_0 \\
  y_1 \\
  y_2 \\
  \vdots \\
  y_{n-1}
\end{bmatrix}
= 
\begin{bmatrix}
  3 & 0 & 1 & \cdots & 0 \\
  0 & 2 & 0 & \cdots & 0 \\
  0 & 0 & 4 & \cdots & 0 \\
  \vdots & \vdots & \vdots & \ddots & \vdots \\
  0 & 2 & 6 & \cdots & 8
\end{bmatrix}
\begin{bmatrix}
  x_0 \\
  x_1 \\
  x_2 \\
  \vdots \\
  x_{n-1}
\end{bmatrix}
\]

- Most values in matrix are zero
  - Note: easy parallelization by parallelizing the different per-row dot products
  - But different amounts of work per row (complicates wide SIMD execution)

- Example sparse storage format: compressed sparse row

values = [ [3, 1], [2], [4], ..., [2, 6, 8] ]
cols = [ [0, 2], [1], [2], ..., ]
row_starts = [0, 2, 3, 4, ... ]
Sparse matrix multiplication with scan

\[
x = [x_0, x_1, x_2, x_3]
\]

\[
\text{values} = [ [3, 1], [2], [4], [2, 6, 8] ]
\]

\[
\text{cols} = [ [0, 2], [1], [2], [1, 2, 3] ]
\]

\[
\text{row\_starts} = [0, 2, 3, 4]
\]

1. Map over all non-zero values: \( \text{products}[i] = \text{values}[i] \times x[\text{cols}[i]] \)
   \( \text{products} = [3x_0, x_2, 2x_1, 4x_2, 2x_1, 6x_2, 8x_3] \)

2. Create flags vector from row\_starts: \( \text{flags} = [1, 0, 1, 1, 0, 0] \)

3. Perform \textbf{inclusive} segmented-scan on \((\text{products}, \text{flags})\) using addition operator
   \( [3x_0, 3x_0+x_2, 2x_1, 4x_2, 2x_1, 2x_1+6x_2, 2x_1+6x_2+8x_2] \)

4. Take last element in each segment:
   \( y = [3x_0+x_2, 2x_1, 4x_2, 2x_1+6x_2+8x_2] \)
Scan/segmented scan summary

- **Scan**
  - Theory: parallelism in problem is linear in number of elements
  - Practice: exploit locality, use only as much parallelism as necessary to fill the machine’s execution resources
    - Great example of applying different strategies at different levels of the machine

- **Segmented scan**
  - Express computation and operate on irregular data structures (e.g., list of lists) in a regular, data parallel way
More operations

- **Group by key**
  - Seq (key, T) —> Seq (key, Seq T)
  - Similar to: sort sequence by key, the performing segmented scan operations on segments with same key

- **Filter**
  - Remove elements from sequence that do not match predicate
Example: create grid of particles data structure on large parallel machine (e.g., a GPU)

- Problem: place 1M point particles in a 16-cell uniform grid based on 2D position
  - Parallel data structure manipulation problem: build a 2D array of lists
- Recall: Up to 2048 CUDA threads per SM core on a GTX1080 GPU (20 SM cores)
Common use of this structure: N-body problems

- A common operation is to compute interactions with neighboring particles.
- Example: given a particle, find all particles within radius $R$.
  - Organize particles by placing them in a grid with cells of size $R$.
  - Only need to inspect particles in surrounding grid cells.
Solution 1: parallelize over cells

- One possible answer is to decompose work by cells: for each cell, independently compute what particles are within it (eliminates contention because no synchronization is required)
  - Insufficient parallelism: only 16 parallel tasks, but need thousands of independent tasks to efficiently utilize GPU
  - Work inefficient: performs 16 times more particle-in-cell computations than sequential algorithm

```c
list cell_lists[16];    // 2D array of lists

for each cell c       // in parallel
    
        for each particle p  // sequentially if (p is within c)
            append p to cell_lists[c]
```
Solution 2: parallelize over particles

- Another answer: assign one particle to each CUDA thread. Thread computes cell containing particle, then atomically updates per cell list.

  - Massive contention: thousands of threads contending for access to update single shared data structure

```c
list cell_list[16];  // 2D array of lists
lock cell_list_lock;

for each particle p  // in parallel
c
    c = compute cell containing p
    lock(cell_list_lock)
    append p to cell_list[c]
    unlock(cell_list_lock)
```
Solution 3: use finer-granularity locks

- Alleviate contention for single global lock by using per-cell locks
  - Assuming uniform distribution of particles in 2D space...
  - ~16x less contention than solution 2

```c
list cell_list[16];  // 2D array of lists
lock cell_list_lock[16];

for each particle p  // in parallel
    c = compute cell containing p
    lock(cell_list_lock[c])
    append p to cell_list[c]
    unlock(cell_list_lock[c])
```
Solution 4: compute partial results + merge

- Yet another answer: generate N “partial” grids in parallel, then
  - Example: create N thread blocks (at least as many thread blocks as SM cores)
  - All threads in thread block update same grid
    - Enables faster synchronization: contention reduced by factor of N and cost of synchronization is lower because it is performed on block-local variables (in CUDA shared memory)
  - Requires extra work: merging the N grids at the end of the computation
  - Requires extra memory footprint: Store N grids of lists, rather than 1
Solution 5: data-parallel approach

Step 1: map
compute cell containing each particle (parallel over input particles)

<table>
<thead>
<tr>
<th>particle_index:</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>grid_cell:</td>
<td>9</td>
<td>6</td>
<td>6</td>
<td>4</td>
<td>6</td>
<td>4</td>
</tr>
</tbody>
</table>

Step 2: sort results by cell (particle index array permuted based on sort)

<table>
<thead>
<tr>
<th>particle_index:</th>
<th>3</th>
<th>5</th>
<th>1</th>
<th>2</th>
<th>4</th>
<th>0</th>
</tr>
</thead>
<tbody>
<tr>
<td>grid_cell:</td>
<td>4</td>
<td>4</td>
<td>6</td>
<td>6</td>
<td>6</td>
<td>9</td>
</tr>
</tbody>
</table>

Step 3: find start/end of each cell (parallel over particle_index elements)

```
particle_cell = grid_cell[index];
if (index == 0)
    cell_starts[particle_cell] = index;
else if (particle_cell != grid_cell[index-1]) {
    cell_starts[particle_cell] = index;
    cell_ends[grid_cell[index-1]] = index;
}
if (index == numParticles-1) // special case for last cell
    cell_ends[particle_cell] = index+1;
```

<table>
<thead>
<tr>
<th>cell_starts</th>
<th></th>
<th></th>
<th></th>
<th>0</th>
<th>2</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>cell_ends</td>
<td></td>
<td></td>
<td>2</td>
<td>5</td>
<td>6</td>
<td></td>
</tr>
</tbody>
</table>

This solution maintains a large amount of parallelism and removes the need for fine-grained synchronization... at cost of a sort and extra passes over the data (extra BW)
Another example: parallel histogram

- Consider compute a histogram for a large sequence of values

```c
int f(float value); // maps array values to bin id’s

float input[N];

int histogram_bins[NUM_BINS]; // assume bins are initialized to 0

for (int i=0; i<N; i++)
    { histogram_bins[f(input[i])]++;
```

- Create a massively parallel implementation of histogram given only map() and sort() on sequences
Another example: parallel histogram (part 1)

```c
void compute_bin(float* input, int* bin_ids) {
    bin_ids[idx] = f(input[idx]);
}

void find_starts(int* bin_ids, int* starts) {
    if (idx == 0 || bin_ids[idx] != bin_ids[idx-1])
        starts[bin_ids[idx]] = idx;
}

float input[N];
int bin_ids[N]; // bin_ids[i] = id of bin that element i goes in
int sorted_bin_idx[N];
int bin_starts[NUM_BINS]; // initialized to -1

// map f onto input to get bin ids of all elements
launch<<<N>>>(compute_bin(input, bin_ids));

// find starting point of each bin in sorted list
sort(N, bin_ids, sorted_bin_idx);
launch<<<N>>>(find_starts(sorted_bin_ids, bin_starts));
```
Another example: parallel histogram

```c
void bin_sizes(int* bin_starts, int* histogram_bins, int num_items, int num_bins) {

    if (bin_starts[idx] == -1) {
        histogram_bins[idx] = 0; // no items in this bin
    } else {

        // find start of next bin in order to determined size of current bin

        // Tricky edge case: if the next bin is empty, then must search forward to find
        // the next non-empty bin
        int next_idx = idx+1;
        while(next_idx < num_bins && bin_starts[next_idx] == -1)
            id++;

        if (next_idx < num_bins)
            histogram_bins[idx] = bin_starts[next_idx] - bin_starts[idx];
        else
            histogram_bins[idx] = num_items - bin_starts[idx];
    }
}

launch<<<NUM_BINS>>>bin_sizes(bin_starts, histogram_bins, N, NUM_BINS);
```
Scatter/gather operations on sequences

- **gather(index, input, output)**
  - `output[i] = input[index[i]]`

- **scatter(index, input, output)**
  - `output[index[i]] = input[i]`
Gather instruction

\texttt{gather(R1, R0, mem\_base);} \quad \text{“Gather from buffer mem\_base into R1 according to indices specified by R0.”}

Array in memory with (base address = mem\_base)

<table>
<thead>
<tr>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>
<th>8</th>
<th>9</th>
<th>10</th>
<th>11</th>
<th>12</th>
<th>13</th>
<th>14</th>
<th>15</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

mem\_base

\begin{array}{ccccccccccc}
  3 & 12 & 4 & 9 & 9 & 15 & 13 & 0 &   &   &   &   &   &   &   \\
\end{array}

Index vector: R0 \quad \text{Result vector: R1}

Gather supported with AVX2 in 2013

But AVX2 does not support SIMD scatter (must implement as scalar loop)

Scatter instruction exists in AVX512

Hardware supported gather/scatter does exist on GPUs.
(still an expensive operation compared to load/store of contiguous vector)
Turning scatter into sort/gather

- \( \text{scatter}(\text{index, input, output}) \)
  
  - \( \text{output}[\text{index}[i]] = \text{input}[i] \)

- Assume elements of index are unique and all elements references in index (scatter is a permutation)

\[
\text{temp} = \text{sort input sequence by values in index sequence} \\
\text{output}[i] = \text{temp}[i]
\]
Turning scatter with atomic sort/map/scan

for all elements in sequence

\[
\text{atomicOp(output[index[i]], input[i])}
\]

Assume elements in index are not unique, so synchronization is required for atomicity!

Sort input sequence according to values in index sequence

\[
[0, 0, 0, 1, 1, 2] \quad [\text{input[2] input[4], input[5], input[0], input[1], input[3]}]
\]

Compute starts of each range of the same index number

\[
[1, 0, 0, 1, 0, 1]
\]

Segmented scan (using ‘op’) each range

\[
\text{op(op(input[2], input[4]), input[5]), op(input[0], input[1]), input[3])}
\]
Data parallel thinking:
- Implementing algorithms in terms of simple (often widely parallelizable, efficiently implemented) operations on large data collections

Turn irregular parallelism into regular parallelism

Turn fine-grained synchronization into coarse (barrier) synchronization

But most solutions require multiple passes over data — bandwidth hungry!
Summary

- Data parallel primitives are basis for many parallel/distributed systems today
- CUDA's Thrust Library
- Apache Spark / Hadoop
